ABSTRACT

Background: Aspergillus lentulus was described as a new species in 2005 but it was isolated from Turkey for the first time.

Case report: A. lentulus was isolated as the cause of pneumonia from a patient who had renal transplantation 4 months ago. The patient received immunosuppressive treatment after transplantation. A. lentulus was isolated from his sputum as an agent in pneumonia developed 4 months after the transplantation. Leukocytes, blastospores, and hyphae were seen in both Gram- and Giemsa-stained smears of the sputum. The isolate was identified by using the Maren A. Klich algorithm and molecular methods and confirmed by the reference laboratory of the CBS Fungal Biodiversity Centre (The Netherlands). In the susceptibility tests of the isolate, minimal inhibitory concentrations for amphotericin B, voriconazole, posaconazole, and caspofungin were found to be 0.5 µg/mL, 0.25 µg/mL, 0.125 µg/mL, and 0.25 µg/mL, respectively. The patient recovered with voriconazole treatment (2x200 mg/day).

Conclusion: The use of the molecular tests is important for identification of A. lentulus strains because they are very easily confused with A. fumigatus strains according to phenotypic characteristics.

Key Words: Invasive pulmonary aspergillosis, immunocompromised host, Aspergillus lentulus

Received: 17.01.2013  Accepted: 02.08.2013

Introduction

Aspergillus fungi are widely distributed all over the world in soil and decayed materials (1). At the same time, these Aspergillus species are the most common agents of invasive infections caused by mould in the world (2). They are in second place after Candida spp. when considering all invasive fungal infections (3).

Invasive aspergillosis is usually seen in an immunocompromised host and is an illness related to haematological malignancy, bone marrow/solid organ transplantation, or corticosteroid therapy (4, 5). Today, as the mentioned risk factors increase, the incidence of this disease increases at the same rate (5). The most common cause of invasive aspergillosis is Aspergillus fumigatus (6, 7). Other causative agents are Aspergillus terreus, Aspergillus niger, Aspergillus flavus, and other species belonging to section Fumigati (5). Recently, A. lentulus has also been reported as a cause of invasive aspergillosis (6, 8, 9).

A. lentulus was described by Balajee et al. (9) as a new species in 2005. Firstly, a variant of the weak sporulated A. fumigatus was isolated from patients with haematopoietic stem cell transplantation as the agent of invasive infection. These strains were found to be different from other species according to characteristics of the phylogenetic origins as well as their different antifungal sensitivities, and they were named as A. lentulus (9). In this paper, the characteristics of the first isolate of A. lentulus in Turkey are presented.

Case Report

The case was a 36-year-old male with chronic renal failure who had been having continuous ambulatory peritoneal dialysis for 8 years. Cadaveric renal tissue was transplanted to the patient approximately 4 months ago. Anti-thymocyte globulin and corticosteroid were initially administered to the patient for immunosuppressive treatment after transplantation. Later, the patient’s therapy was continued with tacrolimus, mycophenolate mofetil, and low-dose corticosteroid. The case was admitted by the Trakya University Hospital in treatment of a cough complaint. He had auscultation sign and radiological infiltration in the right lung. In laboratory investigation, his leucocyte count was 6000/µL in haemogram, ESR was 74 mm/hour, and CRP was 8.44 mg/dL. Leukocytes, blastospores, and hyphae were seen in both Gram- and Giemsa-stained smears of his sputum. A. lentulus was isolated from his sputum as a causative agent of pneumonia that developed 4 months after the renal transplantation. It was again isolated in the second sputum and bronchoalveolar lavage samples. Invasive pulmonary aspergillosis was diagnosed according to clinical, radiological, and microbiological findings in this immunosuppressed host.

The strain was identified by using the Maren A. Klich algorithm and molecular methods. It was incubated for 7 days after inoculation of Czapek Agar (25°C), 20% sucrose Czapek Yeast Agar (25°C), malt extract agar (25°C), and Czapek Yeast Agar (25-37°C). The diameter of Aspergillus colonies were 32 mm, 35 mm, 36 mm, and 41-47 mm, respectively (Figure 1).
The appearance of the colony was downy to powdery in texture and greenish to white in colour. The reverse colour was cream. Branched conidiophore structures were observed in direct microscopic analysis of the strain prepared with Sabouraud Dextrose Agar. Biseriate phialides arising from the round vesicles were also observed (Figure 2). The identification of the A. lentulus strain was confirmed with molecular methods by the reference laboratory of the CBS Fungal Biodiversity Centre (The Netherlands). Its susceptibility was tested by the broth dilution method (10). In the susceptibility tests of the strain, minimal inhibitory concentrations (MICs) for amphotericin B, voriconazole, posaconazole, and caspofungin were found to be 0.5 µg/mL, 0.25 µg/mL, 0.125 µg/mL, and 0.25 µg/mL, respectively. The patient recovered with voriconazole treatment (2x200 mg/day).

**Discussion**

Fungal spores of Aspergillus or the other saprophytes in the air may reach the respiratory system and can easily cause infections in an immunocompromised host (1). According to the order of frequency, A. fumigatus, A. flavus, and A. niger were recently isolated as agents of invasive aspergillosis in our hospital (11). Isolations of A. lentulus defined in 2005 as a kind of new Aspergillus species were reported in America, Japan, South Korea, Australia, and Spain (9, 12). The characteristics of some cases with colonisation or infection caused by A. lentulus in the literature are shown in Table 1 (3, 8, 9, 13, 14). However, an isolation of or infection caused by A. lentulus was not reported in Turkey until today.

Recently, some fungi in section Fumigati have often been misdiagnosed as A. fumigatus. Today, the use of molecular methods is recommended to prevent false identification of the species in the A. fumigatus complex (2, 6). The strain isolated in the present study resembled A. fumigatus according to many features but its branched conidiophore on microscopic examination attracted attention; therefore, it was thought to be of a different kind. The strain was identified as A. lentulus by the reference laboratory to which it was sent for confirmation by molecular methods.

Although the strains of A. fumigatus are intrinsically sensitive to itraconazole, voriconazole, posaconazole, and amphotericin B, A. lentulus strains usually have higher MIC values for these drugs and caspofungin (6, 7, 15). Average MIC values of eight A. fumigatus strains, agents of invasive aspergillosis in our hospital, were 2 µg/mL, 0.25 µg/mL, 0.064 µg/mL, and 0.064 µg/mL for amphotericin B, voriconazole, posaconazole, and caspofungin, respectively (16). The A. lentulus strain in the present study had a fourfold lower MIC for amphotericin B, similar MIC for voriconazole, twofold higher MIC for posaconazole, and fourfold higher MIC for caspofungin in comparison with the A. fumigatus strains. As pointed out by Staab et al. (17), A. lentulus may show in vitro low and variable susceptibility for amphotericin B, itraconazole, voriconazole, and echinocandins. It is interesting that the susceptibility characteristics of the present strain are slightly different to that antifungal susceptibility reported in the literature. It is also interesting that two out of 14 A. lentulus strains are susceptible to itraconazole in the literature (5). Although these susceptibility tests were repeated eight times, the results were not uniform. Thus, modifications in evaluation of the susceptibility tests to solve different susceptibility results were recommended by the authors (5). In the present study, the susceptibility tests were repeated twice and similar results were obtained. It was evaluated positive in terms of its compliance susceptibility tests due to a good clinical response to voriconazole therapy of the patient.

The different sensitivity characteristics of A. lentulus strains compared with A. fumigatus strains should be considered in the choice of empirical treatment. The first condition of suitable empirical antifungal therapy is also correct identification of the agent. The use of molecular tests is important for identification of A. lentulus strains because they are very easily confused with A. fumigatus strains according to phenotypic characteristics.
